

Dependency ordering in the Linux kernel

Will Deacon <will@kernel.org>

The sorry state of dependency ordering

- Hardware** CPU architectures **guarantee** that some dependencies enforce externally-visible ordering between memory accesses
- Performance** Dependency ordering is generally **cheaper** than using explicit fences, particularly where the dependency exists naturally as part of the algorithm.
- Linux** The **kernel relies on dependency ordering** as a basis for RCU, but also to implement ring buffers and parts of the scheduler using volatile casts (`READ_ONCE/WRITE_ONCE`)
- C Compiler** No high-performance implementations exist of `memory_order_consume` and the **kernel does not follow the C11 memory model** anyway.

Types of dependency

Please try to use this terminology!

Control dependency

```
x = READ_ONCE(*foo);  
if (x > 42)  
    WRITE_ONCE(*bar, 1);
```

- Read -> write generally ordered by all CPU architectures
- **Read -> read control dependencies can often be reordered by hardware!**

Data dependency

```
x = READ_ONCE(*foo);  
x += 42;  
WRITE_ONCE(*bar, x);
```

- Read -> write only
- Supported by all CPU architectures

Address dependency

```
x = READ_ONCE(*foo);  
bar = &x[42];  
y = READ_ONCE(*bar);
```

- Read -> read/write
- `rcu_dereference()`
- Ordered by all CPU architectures other than Alpha (where we insert a fence)

Harmful compiler transformations

Converting a read -> read address
dependency into a control dependency
breaks hardware ordering!

Address dependency

```
x = READ_ONCE(*foo);  
bar = &x[42];  
y = READ_ONCE(*bar);
```

Control dependency

```
x = READ_ONCE(*foo);  
if (x == baz)  
    bar = &baz[42];  
else  
    bar = &x[42];  
y = READ_ONCE(*bar);
```

Harmful compiler transformations

Converting a read -> read address
dependency into a control dependency
breaks hardware ordering!

Address dependency

```
seq = READ_ONCE(tkf->seq.sequence);  
tkr = tkf->base + (seq & 0x01);  
now = tkr->base;
```

Control dependency

```
tkr = tkf->base;  
seq = READ_ONCE(tkf->seq.sequence);  
if (seq & 0x01)  
    tkr++;  
now = tkr->base;
```

We actually disable lots of "valid" (read: the standard allows them, but they are completely wrong for the kernel) optimizations because they are wrong.

[...]

So in general, we very much expect the compiler to do sane code generation, and not (for example) do store tearing on normal word-sized things or add writes that weren't there originally etc.

Some discussion points

Can we provide tooling to help the kernel use dependency ordering without disabling compiler optimisations on a case-by-case basis?

- How can we enforce dependencies at the source level?
- Can we detect broken dependencies and/or insert fences?
- Are annotations a non-starter?
- Does LTO make the situation worse?
- Where do we draw the line between “optimising compiler” and “portable assembler”?

Please don't throw the standard at us! :)
